Finding bridges in a graph in O(N+M)

Table of Contents

- Algorithm
- Implementation
- Practice Problems

We are given an undirected graph. A bridge is defined as an edge which, when removed, makes the graph disconnected (or more precisely, increases the number of connected components in the graph). The task is to find all bridges in the given graph.

Informally, the problem is formulated as follows: given a map of cities connected with roads, find all "important" roads, i.e. roads which, when removed, cause disappearance of a path between some pair of cities.

The algorithm described here is based on depth first search and has O(N+M) complexity, where N is the number of vertices and M is the number of edges in the graph.

Note that there also is also the article Finding Bridges
Online - unlike the offline algorithm described here, the
online algorithm is able to maintain the list of all bridges
in a changing graph (assuming that the only type of
change is addition of new edges).

Algorithm

Pick an arbitrary vertex of the graph root and run depth first search from it. Note the following fact (which is easy to prove):

• Let's say we are in the DFS, looking through the edges starting from vertex v. The current edge (v,to) is a bridge if and only if none of the vertices to and its descendants in the DFS traversal tree has a backedge to vertex v or any of its ancestors. Indeed, this condition means that there is no other way from v to to except for edge (v,to).

Now we have to learn to check this fact for each vertex efficiently. We'll use "time of entry into node" computed by the depth first search.

So, let tin[v] denote entry time for node v. We introduce an array fup which will let us check the fact for each vertex v. fup[v] is the minimum of tin[v], the entry times tin[p] for each node p that is connected to node v

via a back-edge (v,p) and the values of fup[to] for each vertex to which is a direct descendant of v in the DFS tree:

$$fup[v] = \min egin{cases} tin[v] \\ tin[p] & ext{for all p for which (v,p) is a} \\ fup[to] & ext{for all to for which (v,to) is} \end{cases}$$

Now, there is a back edge from vertex v or one of its descendants to one of its ancestors if and only if vertex v has a child to for which $fup[to] \leq tin[v]$. If fup[to] = tin[v], the back edge comes directly to v, otherwise it comes to one of the ancestors of v.

Thus, the current edge (v,to) in the DFS tree is a bridge if and only if fup[to] > tin[v].

Implementation

The implementation needs to distinguish three cases: when we go down the edge in DFS tree, when we find a back edge to an ancestor of the vertex and when we return to a parent of the vertex. These are the cases:

- $ullet \ visited[to] = false$ the edge is part of DFS tree;
- $visited[to] = true \ \&\& \ to \neq parent$ the edge is back edge to one of the ancestors;

ullet to = parent - the edge leads back to parent in DFS tree.

To implement this, we need a depth first search function which accepts the parent vertex of the current node.

C++ implementation | Show/Hide

Main function is **find_bridges**; it performs necessary initialization and starts depth first search in each connected component of the graph.

Function IS_BRIDGE(a, b) is some function that will process the fact that edge (a,b) is a bridge, for example, print it.

Note that this implementation malfunctions if the graph has multiple edges, since it ignores them. Of course, multiple edges will never be a part of the answer, so **IS_BRIDGE** can check additionally that the reported bridge does is not a multiple edge. Alternatively it's possible to pass to **dfs** the index of the edge used to enter the vertex instead of the parent vertex (and store the indices of all vertices).
